**Bmi1 Is a Key Epigenetic Barrier to Direct Cardiac Reprogramming**

**Graphical Abstract**

**Highlights**
- shRNA screen identified Bmi1 as a major epigenetic barrier to cardiac reprogramming
- Bmi1 downregulation significantly enhanced iCM generation from mouse fibroblasts
- Bmi1 directly binds to and suppresses cardiogenic loci
- Bmi1 depletion can functionally substitute for Gata4 during iCM conversion

**In Brief**
Qian and colleagues carried out a loss-of-function screen to identify epigenetic factors that modulate reprogramming of fibroblasts into beating cardiomyocytes. They found that repression of Bmi1 enhances reprogramming efficiency and correlates with altered epigenetic status at key cardiogenic loci, resulting in their de-repression.

SUMMARY

Direct reprogramming of induced cardiomyocytes (iCMs) suffers from low efficiency and requires extensive epigenetic repatterning, although the underlying mechanisms are largely unknown. To address these issues, we screened for epigenetic regulators of iCM reprogramming and found that reducing levels of the polycomb complex gene Bmi1 significantly enhanced induction of beating iCMs from neonatal and adult mouse fibroblasts. The inhibitory role of Bmi1 in iCM reprogramming is mediated through direct interactions with regulatory regions of cardiogenic genes, rather than regulation of cell proliferation. Reduced Bmi1 expression corresponded with increased levels of the active histone mark H3K4me3 and reduced levels of repressive H2AK11ub at cardiogenic loci, and de-repression of cardiogenic gene expression during iCM conversion. Furthermore, Bmi1 deletion could substitute for Gata4 during iCM reprogramming. Thus, Bmi1 acts as a critical epigenetic barrier to iCM production. Bypassing this barrier simplifies iCM generation and increases yield, potentially streamlining iCM production for therapeutic purposes.

INTRODUCTION

The adult mammalian heart has limited regenerative capacity and is thus an important target for novel regenerative approaches to replenish lost cardiomyocytes (CMs) after cardiac injury (Laflamme and Murry, 2011; Porrello et al., 2011; Ubil et al., 2014; Xin et al., 2013). Cardiac reprogramming that converts fibroblasts to contractile induced cardiomyocytes (iCMs) by overexpression of cardiac-lineage-specific transcription factors holds great promise as an alternative approach for cardiac regeneration and disease modeling (Addis and Epstein, 2013; Addis et al., 2013; Chen et al., 2012; Fu et al., 2013; Hirai et al., 2013; Ieda et al., 2010; Ifkovits et al., 2014; Jayawardena et al., 2012; Muraoka et al., 2014; Nam et al., 2013; Protze et al., 2012; Qian and Srivastava, 2013; Song et al., 2012; Wada et al., 2013; Wang et al., 2015a; Zhao et al., 2015; Zhou et al., 2015). However, our limited understanding of the molecular mechanism underlying cardiac reprogramming has significantly hindered its potential translational applications.

Epigenetic regulation plays a critical role in shaping and maintaining cellular identities during developmental programming and cellular reprogramming. Recent studies on in vitro cardiac differentiation of embryonic stem cells demonstrated that temporal activation of functionally important cardiac genes requires concerted programmed control of chromatin structure (Paige et al., 2012; Wamstad et al., 2012). Likewise, cellular reprogramming is accompanied by profound changes in the epigenetic landscape (Dhawan et al., 2011; Liang and Zhang, 2013; Luna-Zurita and Bruneau, 2013; Onder et al., 2012; Tursun et al., 2011). This transition in epigenetic status is likely to be involved in suppressing the original cell-type-specific signature and establishing and stabilizing a target cell-type-specific program (Apostolou and Hochedlinger, 2013; Buganim et al., 2013; Papp and Plath, 2013). Epigenetic alterations were also observed at both fibroblast- and CM-specific marker genes during iCM reprogramming (Fu et al., 2013; Ieda et al., 2010). However, how these epigenetic transitions are regulated remains elusive. iCM reprogramming, like other types of cellular reprogramming, is an inefficient and slow process, which is at least in part due to multiple epigenetic barriers that have not been identified. It also remains unclear whether iCM reprogramming shares similar epigenetic mechanisms with induced pluripotent stem cell (iPSC) reprogramming or has its own specific barriers.

Here we report the first shRNA-based loss-of-function screen to explore the role of epigenetic factors in iCM reprogramming. Among the identified epigenetic regulators of iCM reprogramming, the polycomb ring finger oncogene Bmi1 acted as a major epigenetic barrier during the early phase of iCM reprogramming. Genetic and epistasis analyses suggested that the inhibitory effect of Bmi1 on iCM reprogramming was not completely mediated by its downstream effectors involved in cell proliferation such as p16ink4a, p19arf, and p53. Instead, we discovered an uncharacterized role of Bmi1 in directly binding the regulatory regions of several cardiogenic genes including Gata4. Knockdown of Bmi1 caused de-repression of endogenous Gata4 and could...
functionally replace Gata4 to induce beating iCMs. Thus, our work identifies Bmi1 as a critical epigenetic barrier at the early stage of iCM reprogramming and demonstrates that removing this early epigenetic barrier is sufficient to generate functional iCMs with fewer transcription factors.

**RESULTS**

**Loss-of-Function Screen Identified Epigenetic Barriers to, and Facilitators of, iCM Reprogramming**

To identify potential epigenetic regulators of iCM reprogramming, we employed a loss-of-function approach to explore the function of 35 selected components of chromatin modifying or remodeling complexes (Table S1). For each candidate, a pool of shRNAs (four to six independent shRNA constructs) targeting different regions within the gene was used and knockdown efficiency was validated (Table S1 and Figure S1A). The individual shRNA pools were then transduced into neonatal cardiac fibroblasts (CFs) isolated by using explant culture method (ExCFs) from a transgenic α-cardiac muscle heavy chain (αMHC)-GFP reporter mouse (Ieda et al., 2010; Qian et al., 2013) together with retroviruses expressing polycistronic Mef2c/Gata4/Tbx5 (MGT) (Wang et al., 2015a).

Upon transduction of MGT, activation of GFP allowed us to follow the emergence of newly induced iCMs. Furthermore, we used cardiac Trophinin T (cTnT) as an additional differentiated CM marker to monitor CF to CM fate conversion (Figure 1A). iCM reprogramming efficiency was determined by flow cytometry analysis to quantify the percentage of αMHC-GFP+ and cTnT+ cells (Figure 1A). Although to various degrees, knocking down 11 of the 35 epigenetic regulators reduced reprogramming efficiency (Figure 1B and Table S1). Silencing inhibitor of growth family member 1 (Ing1) or lysine (K)-specific demethylase 5B (Kdm5b/Plu1) resulted in at least 2-fold reduction in the percentages of αMHC-GFP+ or cTnT+ cells (Figure 1B and Table S1). Ing1 functions as a reader protein of H3K4me3/2, while Plu1 acts as an H3K4me3/2 demethylase (Table S1). These observations highlight the importance of histone methylation during iCM reprogramming. On the contrary, loss of Plu1 function has been found to enhance iPSC reprogramming (Kidder et al., 2013), suggesting that this histone modifier might be required for iCM reprogramming while impeding reprogramming to pluripotency.

In addition to the factors that were required for iCM reprogramming, we also identified epigenetic regulators that likely acted as barriers to iCM reprogramming (Figures 1B and 1C), shRNA pools against K(lysine) acetyltransferase 7 (KAT7/Myst2), K(lysine) acetyltransferase 6A (KAT6A/Myst3), lysine (K)-specific demethylase 5C (KDM5C/Smcx) or inhibitor of growth family member 5 (Ing5) resulted in a roughly 2-fold increase in iCM reprogramming efficiency (Figure 1C and Table S1). Myst2 and Myst3 belong to the MYSF family of histone acetyltransferases, whereas Smcx functions as an H3K4 demethylase (Table S1). Knockdown of helicase lymphoid specific (HelLS/Lsh/Smrca5) resulted in a 6-fold increase in the percentage of cTnT+ cells (Figures 1B and 1C, Table S1). HelLS encodes a component of the SWI/SNF complex, and targeted deletion of HelLS leads to a genome-wide loss of DNA methylation and perinatal lethality (Geiman et al., 2001). In conclusion, chromatin regulatory factors involved in various aspects of epigenetic regulation function either as facilitators of or barriers to iCM reprogramming.

**Bmi1 Acts as a Critical Epigenetic Barrier to iCM Reprogramming**

Among the 35 candidate epigenetic regulators, ablation of Bmi1, which encodes a polycomb group protein homologous to Drosophila protein posterior Sex Combs (Psc) (van Lohuizen et al., 1991; van der Lugt et al., 1994), resulted in the most significant increase in iCM reprogramming efficiency (Figures 1B and 1C, Table S1). Flow analysis and quantification showed that knocking down Bmi1 led to a 10-fold increase in the percentage of cTnT+ cells (Figures 1B and 1C, Table S1). This significant enhancement of iCM reprogramming efficiency caused by loss of Bmi1 function is in sharp contrast to its positive role in iPSC reprogramming (Moon et al., 2011; Onder et al., 2012). Thus, we decided to focus on exploring the role of Bmi1 during fibroblast conversion into iCM. To further determine the effect of Bmi1 knockdown on iCM reprogramming, we used two individual Bmi1 shRNAs, along with MGT to convert neonatal ExCFs into iCMs. Consistently, silencing Bmi1 with these two shRNAs individually resulted in a significant increase in the percentage of αMHC-GFP+ and cTnT+ cells compared to shNT controls (Figures S1B and S1C). Pooled shBmi1 oligos had a knockdown efficiency of >90% and increased iCM reprogramming efficiency to an even greater degree than individual shBmi1 oligos (Figures S1C and S1D). For the rest of the study, we used shBmi1-pool (referred to as shBmi1) unless otherwise indicated. shBmi1 treatment not only increased the percentage of iCMs but also...
resulted in an increased number of iCMs compared to shNT control treatment. We quantified the absolute numbers of αMHC-GFP+ or cTnT+ iCMs using flow cytometry and observed a significant increase in the numbers of both αMHC-GFP+ and cTnT+ cells (Figure S1E). Additionally, shBmi1-treated, freshly isolated neonatal CFs exhibited a similar increase in reprogramming efficiency and the numbers of αMHC-GFP+ or cTnT+ cells (Figures 1D and 1E).

We next determined if this increased CF to iCM conversion rate could translate into enhanced structural and functional maturation. We performed immunocytochemistry (ICC) on shBmi1- and shNT-treated cultures 2 weeks after infection and found that Bmi1 knockdown resulted in a significantly increased number of cells expressing sarcomeric α-Actinin and cTnT (Figures 1F–1H). In addition, Bmi1 knockdown gave rise to an 88.7% increase in the number of α-Actinin+ iCMs that assembled sarcomeres (Figure 1I). More strikingly, we observed twice as many beating iCMs that exhibited periodic calcium oscillation in shBmi1 cultures as we did in control cultures (Figures 1J–1L, Movie S1, Movie S2, and Movie S3). Furthermore, molecular characterization of the Bmi1-depleted and control cells by examination of the expression of a panel of sarcomere, contractility, and ion channel genes revealed higher expression of these functionally important cardiac genes in the Bmi1-depleted cultures (Figure 1M). Taken together, our data demonstrate that knockdown of Bmi1 remarkably enhances MGT-mediated iCM reprogramming.

To further assess the repressive function of Bmi1 on cardiac reprogramming, we used the following three commonly used reprogramming methods in conjunction with shBmi1 or shNT to generate iCMs from freshly isolated neonatal CFs: (1) the MGT polycistronic construct (Wang et al., 2015a), (2) separate M+G+T (Ieda et al., 2010), or (3) M+G+T plus Hand2 (M+G+T+H) (Song et al., 2012). Interestingly, we observed the highest percentage of αMHC-GFP+ or cTnT+ cells by MGT, but the highest absolute number of cTnT+ cells by M+G+T+H regardless of Bmi1 knockdown (Figures 2A–2F), reflecting varied reprogramming outcomes depending on which marker was used as the readout. Nevertheless, Bmi1 knockdown uniformly increased iCM percentage across all reprogramming conditions (Figures 2A–2F) and exerted the most influence over the MGT transduced cultures (Figures 2A–2F). The significant increase in reprogramming efficiency observed with Bmi1 knockdown under all conditions indicates that depletion of Bmi1 influences cardiac reprogramming mediated by different cocktails and leads to higher reprogramming efficiency (reached to 50% of marker+ iCMs under MGT induction) compared to the corresponding controls.

Furthermore, we validated our findings in multiple cell types of diverse origin, including mouse embryonic fibroblasts (MEFs), neonatal tail fibroblasts (TTFs), adult CFs, adult TTFs, and CD31+ endothelial cells. Upon Bmi1 knockdown, all cell types exhibited a significant increase in the percentage and absolute number of cardiac-marker-positive iCMs 10 days after MGT transduction (Figures 2G–2P). Quantification of flow and ICC analyses also revealed that enhancement of iCM induction varied depending on the cell types assayed (Figures 2G–2P), suggesting potential intrinsic variability of genetic and epigenetic features and cell plasticity among different cell types. To further validate the enhancement of cardiac reprogramming in non-fibroblast CD31+ endothelial cells, we assessed the expression of several sarcomere and ion channel markers, including Myh6, Myl7, Actc1, Pln, Slc8a1, Scn5a, Cacna1c, Ryr2, and Myl2, and we found that these markers were more highly expressed in shBmi1-treated cells, especially the ion channel marker genes (Figure S2A). Thus, Bmi1 knockdown enhances iCM reprogramming under a variety of conditions and across diverse cell types.

Given the opposing effects of Bmi1 depletion on iCM reprogramming and iPSC reprogramming, we next asked if Bmi1 acted as a general repressor of somatic reprogramming/transdifferentiation or functioned specifically as a repressor of iCM reprogramming. To this end, we generated induced neurons (iNs) from MEFs by following a recently reported protocol (Xue et al., 2013) with shBmi1 or shNT. The efficiency of iN reprogramming was assessed using ICC of neuron marker microtubule associated protein 2 (MAP2) (Figure S2B). Although Bmi1 knockdown appeared to alter the morphology of the MAP2+ iNs (Figure S2B), it did not have any effect on the number of MAP2+ cells (Figure S2C). Further analysis revealed that there was no significant change in the expression levels of additional neuronal markers such as class III β-tubulin (Tubb3) and Nestin (Nes) with shBmi1 compared to the control (Figure S2D). These results indicate that Bmi1 does not regulate direct neuron reprogramming but rather acts as a specific repressor of the iCM reprogramming.

### Bmi1 Functions at the Early Stage of iCM Reprogramming

Next, we sought to determine the temporal window for silencing Bmi1 to achieve an enhancement in iCM induction. We performed flow analysis and quantified the percentage of αMHC-GFP+ and cTnT+ cells generated from shBmi1- and shNT-treated reprogramming ExCFs at a series of time points. Enhancement in iCM reprogramming efficiency by shBmi1 occurred as early as day 3 (Figures 3A and 3B). Likewise, western blot analysis indicated that Bmi1 depletion resulted in a significant upregulation of cardiac marker αMHC-GFP protein expression as early as day 3 (Figure 3C). These observations were further confirmed by the higher expression of a panel of CM marker genes in shBmi1-treated reprogramming fibroblasts at day 3, suggesting an effect of Bmi1 knockdown on cardiac fate acquisition at the early stage of reprogramming (Figure 3D).

To further define the critical time window for Bmi1 knockdown, we introduced Bmi1 shRNAs into neonatal ExCFs at 0, 1, 2, 3, or 5 days after MGT transduction (Figure 3E). Interestingly, we found that iCM reprogramming efficiency as indicated by the percentages of αMHC-GFP+ or cTnT+ cells was reliably increased only if shBmi1 was introduced within 3 days of MGT infection (Figures 3F and 3G). Depletion of Bmi1 at 5 days after MGT transduction did not noticeably affect iCM generation (Figures 3F and 3G). Moreover, reasoning that chromatin remodeling is a prerequisite step to cell fate conversion, we asked if removing the epigenetic barrier by knocking down Bmi1 prior to the introduction of MGT could lead to a similar enhancement. Fibroblasts were infected with shBmi1-puro lentiviruses and cultured under puromycin selection for 3 days before MGT transduction (Figure 3H). Flow cytometry analysis showed that shBmi1-treated neonatal ExCFs also had significantly higher...
Figure 2. Knockdown of Bmi1 Enhanced the Conversion of Diverse Cell Types into iCM When Different Cocktails Were Used

(A–F) Representative flow plots with quantification (A–C) and ICC images with quantification (D–F) for αMHC-GFP+ and cTnT+ cells reprogrammed from fresh CFs 10 days after viral infection. DAPI (blue) was used to stain nuclei. Scale bars, 400 μm.

(G–P) Representative flow plots with quantification and ICC images with quantification for cardiac-marker-gene-positive cells (as indicated) reprogrammed from MEFs (G and H), neonatal TTFs (I and J), adult CFs (K and L), adult TTFs (M and N), and CD31+ endothelial cells (O and P) 10 days after viral infection. Scale bars, 200 μm. For each experiment, n = 3–6 (except n = 20 for E and F; n = 10 for H, J, L, N, and P); averaged numbers from technical duplicates or triplicates were used for statistics. Error bars indicate mean ± SEM; *p < 0.05, **p < 0.01. See also Figure S2.
percentages of αMHC-GFP+ and cTnT+ cells compared to those of the controls (Figure 3I). These data suggest that Bmi1 functions during the early stage of iCM reprogramming and that knockdown of Bmi1 must occur within the first 3 days of or prior to MGT introduction to enhance iCM reprogramming.

Bmi1 Suppresses iCM Reprogramming Independent of Its Role in Regulating Cell Proliferation

One of the well-documented functions of Bmi1 is to regulate cell proliferation and senescence through its downstream effectors p16\(^{INK4a}\), p19\(^{Arf}\), and p53 (Jacobs et al., 1999; Park et al., 2004). We asked if the enhancement of iCM reprogramming by Bmi1 knockdown was mediated through an upregulation of p16\(^{INK4a}\) (isoform 2 of Cdkn2a), p19\(^{Arf}\) (isoform 1 of Cdkn2a), or p53. We first analyzed their expression in control shNT- and shBmi1-infected reprogramming fibroblasts and found that Bmi1 depletion indeed resulted in an upregulation of the expression of these target genes during iCM reprogramming (Figure S3A). We then knocked down Bmi1 and its target genes simultaneously to determine if the increased reprogramming efficiency by Bmi1 knockdown could be reversed by silencing Bmi1 target gene expression. qRT-PCR analysis indicated that we knocked down the expression of Bmi1 target genes by at least 90% (Figure S3B). Interestingly, quantification of flow cytometry analysis showed that the double knockdown cultures exhibited a significant increase in the percentages of αMHC-GFP+ and/or cTnT+ cells compared to the controls (Figure 4A), suggesting that the inhibitory effect of Bmi1 on iCM reprogramming was unlikely to be completely mediated by these downstream targets.

To further assess the effect of p53 or p19\(^{Arf}\) ablation on shBmi1-mediated enhancement of iCM reprogramming, we genetically ablated these genes by infecting neonatal ExCFs isolated from p53\(^{−/−}\) or p19\(^{Arf}\)\(^{−/−}\) floxed mice with Ad-Cre-eGFP (Figures 4B–4E, S3C, and S3D). This approach allowed us to simultaneously excise the genes and label infected cells with eGFP. Ad-CMV-GFP infection was served as a control. qRT-PCR analysis revealed that p53 or p19\(^{Arf}\) expression in the Ad-Cre-eGFP infected fibroblasts was significantly reduced compared to that in the Ad-CMV-GFP infected ones (Figure S3C). These cells were then infected with MGT plus shBmi1 or shNT, and analysis of iCM markers was conducted on the GFP+ population of null or wild-type (fl/fl) control fibroblasts (Figure 4B). We observed that reprogramming efficiency of both p53 null and control CFs was significantly increased by shBmi1 compared to shNT control (Figures 4C and 4D). Likewise, iCM reprogramming efficiency enhanced by Bmi1 depletion was not suppressed by targeted deletion of p19\(^{Arf}\) (Figure 4E). Interestingly, we found that the
expression of $p16^{INK4a}$ increased when $p53$ or $p19^{ARF}$ was knocked down and $p19^{ARF}$ was slightly upregulated upon $p53$ or $p16^{INK4a}$ depletion (Figure S3E), suggesting compensatory mechanisms between $p53$, $p16^{INK4a}$, and $p19^{ARF}$. Therefore, we conducted double and triple knockdowns of $p53$, $p19^{ARF}$, and $Cdkn2a$ to assess their roles in shBmi1-mediated enhancement of cardiac reprogramming. Flow cytometry analysis demonstrated that Bmi1-depleted cultures exhibited lower but still significant increases in the percentage of $\alpha$MHC-GFP+ or cTnT+ cells compared to control cultures even when $Cdkn2a$ and $p53$ were simultaneously silenced (Figure 4F). To further determine if Bmi1 functions through these genes, we tested if overexpression of each could recapitulate the shBmi1 phenotype. Consistently, we found that overexpression of $p53$, $p16^{INK4a}$, or $p19^{ARF}$ did not enhance and sometimes even lowered the percentages of $\alpha$MHC-GFP+ or cTnT+ cells in MGT-transduced cultures (Figures S3F and S3G). Thus, the well-known downstream targets $p53$, $p16^{INK4a}$, and $p19^{ARF}$ are unlikely to be the major downstream mediators of Bmi1 in cardiac reprogramming.

Based on previous reports that Bmi1 and its downstream targets are involved in cell proliferation and senescence (Jacobs et al., 1999; Levine, 1997; Quelle et al., 1995; Sharpless and DePinho, 1999), we sought to determine the requirement of cell proliferation in shBmi1-mediated iCM reprogramming. We used Mitomycin C (MMC), a commonly used inhibitor of cell proliferation, to block CF proliferation 2 days after MGT and shBmi1 or shNT transduction and examined the effect on shBmi1-mediated enhancement of iCM reprogramming (Figure 4G). Interestingly, although MMC treatment inhibited CF proliferation as evidenced by the lack of Ki67 staining in the nuclei of treated cells (Figure 4I), it did not have any noticeable effect on shBmi1-mediated enhancement of iCM reprogramming (Figures 4H and 4I). Next, we added MMC before the introduction of shBmi1 or shNT transduction and examined the effect on $\alpha$MHC-GFP+ or cTnT+ cells compared to control cultures even when $Cdkn2a$ and $p53$ were simultaneously silenced (Figure 4F). To further determine if Bmi1 functions through these genes, we tested if overexpression of each could recapitulate the shBmi1 phenotype. Consistently, we found that overexpression of $p53$, $p16^{INK4a}$, or $p19^{ARF}$ did not enhance and sometimes even lowered the percentages of $\alpha$MHC-GFP+ or cTnT+ cells in MGT-transduced cultures (Figures S3F and S3G). Thus, the well-known downstream targets $p53$, $p16^{INK4a}$, and $p19^{ARF}$ are unlikely to be the major downstream mediators of Bmi1 in cardiac reprogramming.

To test if Bmi1 modulated chromatin status of the cardiogenic genes during the early stage of reprogramming, we performed ChIP-qPCR of H2AK119ub, H3K4me3, and H3K27me3 on Bmi1-depleted and control MEFs that had been transduced with MGT for 3 days. The positive and negative controls for ChIP-qPCR of each mark are shown in Figure S4D. Upon Bmi1 depletion, H2AK119ub at the cardiogenic loci was completely removed (Figures 5F and S4E), consistent with Bmi1’s role in PRC1 assembly to promote monoubiquitination of H2AK119ub. Additionally, in the absence of Bmi1, H3K4me3 levels were moderately increased at the regulatory regions of $Gata4$, $Isil$, $Pitx2$, and $Tbx20$ near where Bmi1 binds (Figures 5G and S4E). Interestingly, the most significant enhancement of H3K4me3 level was detected at the $Gata4$ locus (Figure 5G). In contrast, H3K27me3 modifications at the same loci were barely affected by Bmi1 knockdown (Figures 5H and S4E). We only detected a decrease in H3K27me3 modification in the P2 region of $Pitx2$ and T3 region of $Tbx20$ (Figure 5H). The $Smad6$ locus that was not bound by Bmi1 exhibited low levels of H2AK119ub and H3K27me3. In addition, H3K4me3 levels at $Smad6$ were unaltered by loss of Bmi1 (Figures S4D and S4E, lower panel). Consistent with the increase in the level of H3K4me3 and a major loss of H2AK119ub at the loci, the endogenous mRNA expression of $Gata4$, $Isil$, $Pitx2$, and $Tbx20$ was significantly upregulated by Bmi1 knockdown during iCM reprogramming (Figures 5I). In contrast, Bmi1 knockdown did not affect the expression levels of the genes ($Nkx2-5$ and $Hand2$) whose loci exhibited reduced H2AK119ub, but unaltered H3K4me3 levels (Figures 5I, S4E, and S4G). These data suggest that removal of the repressive mark H2AK119ub is not sufficient to induce the...

expression of all the Bmi1-bound cardiogenic genes. The increase in the level of H3K4me3 in addition to a loss of H2AK119ub, however, is more closely correlated with derepression of cardiogenic gene expression.

In order to determine if Bmi1 only repressed the expression of the cardiogenic genes during iCM reprogramming, we re-analyzed the ChIP-seq data (Bernstein et al., 2012; Gargiulo et al., 2013; Paige et al., 2012; Wamstad et al., 2012) and identified Bmi1 binding peaks that were overlapped with H3K27me3 and H3K4me3 binding sites at other lineage loci (Figure S4H). We carefully selected representative loci encoding regulators of other lineages, including Zic1 and Sox2 (neuron), Pax2 and Sall1 (kidney), and Nkx6-1 and Sox9 (pancreas) to determine the regulation by Bmi1 during iCM reprogramming (Figure S4H). We found that only two loci (Pax2 and Nkx6-1) had Bmi1 binding peaks that overlapped with H2AK119ub, Ring1B, and EzH2 binding sites and upregulated their expression upon Bmi1 knockdown (Figures S4H–S4K). However, Bmi1 knockdown did not have any noticeable effect on gene expression of other loci (Figure S4J).

Taken together, our data suggest that Bmi1 regulates a set of critical cardiogenic factors through direct interactions to their regulatory regions to modulate their chromatin status and expression.

**iCM Reprogramming using Two Transcription Factors, Mef2c and Tbx5**

We were intrigued to find that among the identified targets of Bmi1, Gata4, one of the transcription factors used for iCM reprogramming (Addis et al., 2013; Fu et al., 2013; Ieda et al., 2010; Iffovits et al., 2014; Inagawa et al., 2012; Nam et al., 2013; Qian et al., 2012; Song et al., 2012), was most significantly upregulated in Bmi1-depleted fibroblasts (Figure S4I). Moreover, Gata4 can function as a pioneer transcription factor that binds to its target sites on nucleosomes or compacted chromatin (Cirillo et al., 2002). Because removing Bmi1 de-repressed endogenous Gata4 and other cardiogenic genes, we postulated that Bmi1 depletion could replace Gata4 in reprogramming fibroblasts into functional iCMs. We systematically evaluated all possible two or one cardiogenic reprogramming factor combinations for their capacity to reprogram shNT or shBmi1 fibroblasts into iCMs. Flow cytometry analysis revealed that only Mef2c in combination with Tbx5 (M+T) efficiently converted shBmi1, but not the shNT control, fibroblasts into iCMs that expressed CM marker gene expression (Figure 6A).

Next, to determine if iCM generation could be achieved with a single vector, we generated two polycistronic constructs to express Mef2c and Tbx5 in a single mRNA (MT and TM, Figure 6B). The construct with Mef2c at the first position resulted in a higher reprogramming efficiency than the other (Figures 6C and 6D), consistent with our previous finding that stoichiometry of the reprogramming factors influences iCM reprogramming (Wang et al., 2015a). Moreover, the capability of MT plus shBmi1 to reprogram fibroblasts into αMHC-GFP+ and/or cTnT+ cells was abolished upon the depletion of Gata4 (Figures 6E, S5A, and S5B), suggesting that Gata4 was one of the major downstream effectors of Bmi1 during iCM reprogramming. Importantly, iCMs generated by MT overexpression with Bmi1 knockdown not only turned on cardiac marker gene expression, but also assembled sarcomere structures and exhibited calcium oscillation and spontaneous contraction after 2–4 weeks of culture (Figures 6F–6H, Movie S4, and Movie S5), while none of these features were observed with shNT and MT co-infected fibroblasts. Taken together, our results demonstrate that, after removing epigenetic barriers by Bmi1 depletion, Mef2c and Tbx5 are sufficient to reprogram fibroblasts into functional beating iCMs.

**DISCUSSION**

In this study, we performed a functional screen to identify epigenetic regulators of direct cardiac reprogramming. Knocking down a selected set of epigenetic modifiers either increased or reduced iCM reprogramming efficiency, highlighting the importance of epigenetic regulation in iCM reprogramming. Specifically, we found that Bmi1 functioned as a major epigenetic barrier at the early stage of iCM reprogramming. Through a series of epistatic analyses, we demonstrated that the effect of silencing Bmi1 on cardiac reprogramming was unlikely mediated by its known targets p16INK4a, p19ARF, or p53. In an effort to explore the underlying mechanism, we found that Bmi1 directly bound to a set of key cardiogenic loci that are co-occupied by other PRC components. Knockdown of Bmi1 resulted in a major loss of H2AK119ub and an increase in H3K4me3 levels at these

cardiac loci and de-repression of cardiogenic gene expression. This is consistent with previously published findings that H2AK119 monoubiquitination by PRC1 is associated with gene repression (Cao et al., 2005; Wang et al., 2004). It is also possible that knockdown of Bmi1 de-compacted chromatin and increased DNA accessibility (Abdouh et al., 2016; Eskeland et al., 2010; Francis et al., 2004; Levine et al., 2002; Shao et al., 1999), thereby de-repressing Gata4 and the other

Figure 5. Bmi1 Knockdown Resulted in Acquisition of Active Chromatin Status at the Cardiac Loci
(A) The density of Bmi1, H3K4me3, and H3K27me3 ChIP-seq reads at the indicated gene loci. The gene name initial followed by numbers denotes a series of amplicons that correspond to the binding sites.
(B–H) ChIP-qPCR for Bmi1 (B), H2AK119ub (C), Ring1B (D), or Ezh2 (E) on MEFs at indicated cardiac gene loci. NC (unrelated genomic locus) was used as a negative control.
(F–H) ChIP-qPCR for H2AK119ub (f), H3K4me3 (g), and H3K27me3 (h) at cardiac gene loci on MEFs 3 days after transduction of MGT and shRNA targeting Bmi1 or control.
(I) qRT-PCR of endogenous cardiac gene expression on shNT or shBmi1-infected MGT-expressing MEFs at different time points. Expression at reprogramming day 0 was set as 1. RQ stands for relative quantification.

For each experiment, n = 3–6; averaged numbers from technical duplicates were used for statistics. Error bars indicate mean ± SEM; *p < 0.05, **p < 0.01. n.s., not significant. See also Figure S4.

Figure 6. Mef2c and Tbx5 Reprogrammed Bmi1-Depleted Fibroblasts into iCMs
(A) Quantification of flow analyses for aMHC-GFP+ or cTnT+ cells on shNT- or shBmi1-infected ExCFs expressing different combinations of Mef2c, Gata4, and Tbx5.
(B) Schematics of the two bicistronic vectors encoding Mef2c and Tbx5 in different splicing orders.
(C) Quantification of flow data in (B).
(D) Quantification of flow analyses for aMHC-GFP+ (left) and cTnT+ (right) cells on MT-transduced ExCFs co-injected with shRNA targeting Bmi1, Gata4, or non-targeting control shNT or shTubo as indicated.
(E) Representative flow contour plots of aMHC-GFP+ and cTnT+ cells derived from MT and shBmi1 co-infected fresh CFs 4 weeks after viral transduction. The corresponding movie is shown in Movie S5. Scale bar, 100 μm.

cardiogenic genes. Interestingly, this de-repression of endogenous Gata4 by Bmi1 depletion could substitute for exogenous Gata4 in reprogramming fibroblasts into beating iCMs, demonstrating that removing certain epigenetic barriers could allow efficient iCM generation with fewer transcription factors.

To the best of our knowledge, the screen we performed in this study represents the first loss-of-function screen to study the role of chromatin-associated proteins in iCM reprogramming. Although our shRNA-based screen was not genome-wide, and nor does it cover all epigenetic factors, this study provides proof-of-concept evidence demonstrating the feasibility of an RNAi-mediated functional screen to identify key epigenetic barriers to iCM reprogramming. Given the functional conservation of many epigenetic regulators, especially Bmi1 (98% identity at protein level), between mouse and human, it is likely that removing similar epigenetic barriers in human fibroblasts will lead to improved generation of human iCMs for clinical studies. Furthermore, the platform and conditions described in this study could be leveraged to develop high-throughput large-scale loss-of-function screens. In combination with other approaches such as single-cell omics, it will be possible in the near future to identify each barrier during iCM reprogramming and to leverage this knowledge to alleviate the roadblocks to enhance and accelerate iCM reprogramming.

In addition to Bmi1, we identified a set of epigenetic factors that function as facilitators of or barriers to cardiac reprogramming. These results will stimulate follow-up studies to further interrogate the role of epigenetic factors in iCM reprogramming. Of particular note is the finding that knocking down three MYST histone acetyltransferase family members modestly promoted iCM reprogramming (Figure 1C and Table S1), highlighting the importance of histone acetylation in iCM reprogramming. This finding also suggests possible functional redundancy and compensation among members of epigenetic regulators that belong to the same family. While knocking down Plut1 enhanced iPSC reprogramming (Kidder et al., 2013), silencing Plut1 remarkably reduced iCM reprogramming efficiency (Figures 1B, Table S1). Likewise, we observed an opposite effect of Bmi1 knockdown on iCM versus iPSC reprogramming efficiency and transdifferentiation of neural stem cells (Moon et al., 2011; Onder et al., 2012). Meanwhile, silencing the Ink4a/Arf locus, the well-known downstream target repressed by Bmi1 that functions as a barrier to iPSC and neuronal reprogramming (Li et al., 2009; Price et al., 2014), did not exhibit any noticeable effect on cardiac reprogramming. Our work thus suggests that direct lineage reprogramming, or at least iCM reprogramming, might employ distinct epigenetic regulatory mechanisms from iPSC reprogramming to directly convert one somatic cell type to another.

**EXPERIMENTAL PROCEDURES**

**Primary Cell Cultures**

Hearts and tail tips from neonatal pups (day 1.5) or adult mice (4 weeks) were isolated for explant culture. After 7 days, explant cells were separated by magnetic cell sorting (MACS) so we could obtain Thy1.2+ neonatal or adult CFs and TFFs. CD31+ endothelial cells were derived from explant culture of neonatal hearts by MACS. Fresh CFs were derived from neonatal hearts and underwent MACS via anti-Thy1.2 antibody (Miltenyi Biotec) as described previously (Wang et al., 2015a, 2015b). MEFs were prepared as previously described (Jozefczuk et al., 2012). Detailed descriptions of the isolation of each cell type are available in the Supplemental Information.

**Viral Packaging and Direct Reprogramming**

The protocol of viral packaging is as described in the Supplemental Information. To generate iCMs, fibroblasts or CD31+ endothelial cells were transduced with MGT retroviruses and lentiviruses expressing shRNAs in iCM media (10% FBS of DMEM/M199 [4:1]). At the indicated time points, reprogramming cells were harvested for analyses. For the beating assay, freshly isolated CFs were used. After viral infection and 10 days of culture in iCM media, cells were changed into StemPro-34 SF medium (SPF34, Gibco) supplemented with GlutaMAX (Gibco), Ascorbic acid (Sigma), VEGF, bFGF, and FGF10 (all from R & D Systems). Four to six weeks after viral infection, the number of spontaneously beating cells was counted under an EVOS microscope (40x). Detailed protocols of iCM and IN generation are available in the Supplemental Information.

**Flow Cytometry and ICC**

Flow cytometry analysis and ICC were performed as previously described (Wang et al., 2015a, 2015b). The experimental procedure and antibody information are available in the Supplemental Information.

**qPCR, ChIP, and Western Blot**

Total RNA was isolated with Trizol (Invitrogen) and reverse-transcribed into cDNA using SuperScript III Reverse Transcriptase (Invitrogen). qRT-PCR was performed using the ABI ViiA 7 Real-Time PCR system (Applied Biosystems) and the Power SYBR Green PCR Master Mix (Applied Biosystems) or Taqman Gene Expression Master Mix (Taqman, ABI) according to the manufacturer’s instructions. The primer sequences and Taqman probes used for qRT-PCR are provided in Table S2. ChIP was performed on MEFs according to a previously described protocol (Cai et al., 2013) with minor modification as described in the Supplemental Information. Western blots were performed as described previously (Wang et al., 2015a). Antibody information is available in the Supplemental Information.

**SUPPLEMENTAL INFORMATION**

Supplemental Information for this article includes five figures, two tables, five movies, and Supplemental Experimental Procedures and can be found with this article online at http://dx.doi.org/10.1016/j.stem.2016.02.003.

**AUTHOR CONTRIBUTIONS**

Y.Z. designed and performed experiments, analyzed data, and wrote the manuscript. L.W. designed and performed experiments and analyzed data. H.R.V. performed experiments, analyzed data, and wrote the manuscript. Z.L., S.A., and C.Y. performed experiments and commented on the manuscript. R.L., J.-D.F., and G.G.W. provided critical reagents and comments on the manuscript. J.L. supervised the work and wrote the manuscript. L.Q. supervised the work, designed the experiments, analyzed data, and wrote the manuscript.

**ACKNOWLEDGMENTS**

We are grateful for the expert technical assistance from the UNC Flow Cytometry Core and UNC Microscopy Core. We thank members of the Qian and Liu laboratories and Drs. V. Bautch, J. Taylor, and C. Mack for helpful discussions and critical reviews of the manuscript. H.R.V. is supported by an NIH T32 training grant HL069768-14 (PI, Nobuyo Maeda) and a UNC Pathology Sylke Scholarship. R.L. is supported by a postdoc fellowship from Lymphoma Research Foundation. This study was supported by American Heart Association (AHA) Scientist Development Grant 13SDG1458035 to J.D.F., NCI R00 Award CA151683 to G.G.W. (G.G.W. is a Kimmel Scholar of Sidney Kimmel Foundation for Cancer Research), NIH/NHLBI R00 HL109079 grant to J.L., and American Heart Association (AHA) Scientist Development Grant 13SDG17060010 and the Ellison Medical Foundation (EMF) New Scholar Grant AG-N5-1064-13 to L.Q.
